Concurrency Control for Transactions with Priorities*

Keith Marzullo†

Department of Computer Science

April 30, 1989

Abstract

Priority inversion occurs when a process is delayed by the actions of another process with less priority. With atomic transactions, the concurrency control mechanism can cause delays, and without taking priorities into account can be a source of priority inversion. In this paper, three traditional concurrency control algorithms are extended so that they are free from unbounded priority inversion.

Keywords: Priority inversion, concurrency control, real–time databases.

In a real–time system, the actions of some process may be more urgent than those of another. For example, the first process may need to synchronize with a physical process and sp must must a deadline. If both processes have access to common resources that cannot be shared, the less urgent process may delay the more urgent one by holding onto the resource. This situation

*Submitted to the *10th Real–Time Systems Symposium*, Los Angeles, December 1989.

†This work was supported by the Defense Advanced Research Projects Agency (DoD) under ARPA order 6037, Contract N00140-87-C-8904 The views, opinions, and findings contained in this report are those of the authors and should not be construed as an official Department of Defense position, policy, or decision.

is commonly called a *priority inversion* [7,4]. There are several approaches to this problem, but the simplest is to simply force the less urgent process to relinquish the resource in favor of the more urgent process. *Priority schedulers* are an example of the implementation of this strategy[1].

In database management systems, the concurrency control mechanism is a scheduler through which a process may be delayed by the actions of another process. In this paper, some common concurrency control algorithms are extended so that priority inversions are detected and broken. Transactions will inherit their process's priority, and a transaction will be aborted or delayed if it could delay a more urgent transaction. A transaction is delayed while a less urgent transaction is aborted; we assume that aborts have a fixed overhead and can be taken into account when determining the running time of a transaction.

In this paper, we assume that the transactions submitted by a process are not known *a priori*. The schedulers presented here guarantee that the actions of a transaction cannot be delayed for more than a bounded time by the actions of transactions with less priority. A transaction, however, may be starved by the actions of transactions with more priority. In practice, these kinds of concurrency control algorithms are important for data base systems that support real–time transactions ([8], [1]). They are also important for real–time process control problems with concurrently accessed shared data.

We make the somewhat unusual assumption that priorities are assigned from a partial order rather than a total order. By doing so, we subsume the more typical priorities. We also allow more flexibility in specifying the inadmissible delays; with a total order, we may needlessly constrain the system. We also assume priorities are statically assigned.

This is not a practical paper, in that we have not implemented the algorithms presented here. Concurrency control algorithms are developed by making some decisions on what the equivalent serial order should be. Our goal in this paper is to re-examine these decisions when priorities are also considered. The amount of complexity some of these algorithms took on is surprising. There are some comments on the practical application of these

[1] In this paper, the more urgent process will be said to have *more priority* than the less urgent process.

algorithms in the conclusions of the paper.

In section 1, we describe the properties a concurrency control mechanism must have if it is to support transactions with priorities. In section 2 we develop a general concurrency control mechanism based on *serialization graph testing* algorithms that detects priority inversions. While easy to understand, such algorithms are complex to implement since a directed graph must be maintained and updated with each operation submitted to the scheduler.

There are two popular concurrency control mechanisms where the scheduler use a much simpler data structure at a cost of reduced concurrency. One (*two–phase locking*) delays operations to ensure serializability while the other (*timestamp order*) aborts operations to ensure serializability. In section 3 we show the typical extension of two–phase locking does prevent priority inversion when the priorities are drawn from a connected order. In section 4 we develop a timestamp order mechanism that detects priority inversion.

In this paper, we follow the notation and system model found in [2].

1 Concurrency Control

Suppose we have a set of processes submitting operations under transactions to a database scheduler. Each process can submit an unspecified number of transactions.

There exists a partial order $\succ$ of priorities over the transactions, where $p_1 \succ p_2$ means process 1 has priority over process 2. A transaction T_i submitted by p_i has the same priority as p_i, so we can also write expressions like $T_1 \succ T_2$. The database scheduler knows $\succ$ but has no other information about the transactions any process will submit. A transaction's priority is static; it cannot be changed by the scheduler or the process submitting the transaction.

Our goal is to devise a concurrency control algorithm that:

1. ensures the resulting execution is serializable, and

2. does not delay nor reject an operation of T_i due to the action of T_j when $T_i \succ T_j$.

In general, a scheduler can delay, reject or accept operations in order to guarantee the resulting execution is serializable. Typical schedulers abort a transaction by rejecting one of its operations. In our schedulers, a transaction will be aborted when an operation is submitted by another transaction with more priority.

The scheduler will also ensure that properties other than serializability are met by the resulting execution. For example, suppose a transaction T_2 reads the value of a variable x written by transaction T_1. It is a bad idea to let T_2 commit before T_1 terminates. If T_1 decides to abort, T_2 will have committed using a value that was not produced by a committed transaction, possibly leaving the database in an inconsistent state. So, a scheduler should delay the commit from T_2 until T_1 decides to commit or abort. The property preserved by this delaying action is called *recoverability.*

A more dramatic delay is a *cascaded abort.* Using the above example, since T_2 has read x written by T_1, if T_1 decides to abort, then T_2 must also abort. Again, the scheduler can prevent this condition by delaying some operations. For example, the read of x by T_2 could have been delayed until it was after the termination of T_1.

In both cases, the delay of a transaction (T_2) was caused by a transaction (T_2) reading a value from an uncommitted transaction (T_1). This is a priority inversion when $T_2 \succ T_1$. The priority inversion can be represented graphically. A *reads from graph* (or *RFG*) is a directed graph with all currently active transactions as nodes. There are two kinds of edges in a *RFG.* A *priority edge* from T_i to T_j is drawn with a dashed arrow, and indicates $T_i \succ T_j$. A *reads from* edge from T_i to T_j is drawn with a solid arrow and indicates there is a value x that was written by T_i and later read by T_j. Figure 1 is a *RFG* showing $T_2 \succ T_3$, T_2 has read from T_1 and T_1 has read from T_3. A *cycle* in a *RFG* that that contains one priority edge represents a potential priority inversion. For example, in Figure 1 aborting transaction T_3 will force the abort of T_2 via T_1. We will call such cycles *priority inversion cycles.*

The following theorem argues this more formally.

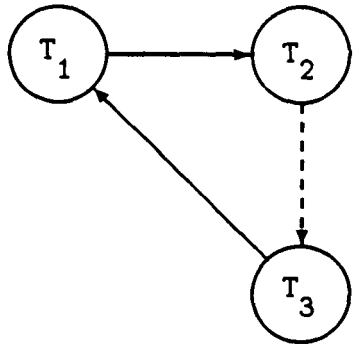

Figure 1: Reads–From Graph

Theorem 1 *If the* RFG *of a set of transactions contains a priority inversion cycle, a priority inversion can occur.*

Proof: Suppose we have a *RFG* that contains such a a cycle. Let the two transactions with the priority edge between them be T_i to T_j such that $T_i \succ T_j$. By the definition of a *RFG*, T_j is active. If T_i wishes to commit, it must delay until $T - j$ commits; otherwise, the resulting execution would not be recoverable. Additionally, if T_j aborts T_i must (transitively) abort. Both cases represent a priority inversion. □

A *purely conservative scheduler* is a scheduler that never rejects an operation (thereby aborting the transaction submitting the rejected operation); it only delays operations until it is safe to execute them. Theorem 1 implies that there are no purely conservative schedulers that avoid priority inversion. Suppose such a scheduler existed, and it were submitted the operation $w_j x$ where $p_i \succ p_j$. By theorem 1, if T_i were to submit the operation $r_i x$, it would introduce the possibility of a priority inversion. So, the scheduler must delay the write operation until it knows that T_i will not submit a $r_i x$ before T_j commits. Since the nature of the transactions submitted by p_i are unknown to the scheduler, it must delay $w_j x$ forever.

Theorem 1 doesn't give a complete characterization of all priority inversions; it only deals with those due to cascaded aborts. For example, suppose we have the following history with $T_i \succ T_j$:

$$w_i x;\ w_j x;\ w_j y;\ c_j;\ w_i y$$

At this point, T_i must abort due to the actions of T_j; otherwise, the execution will not be serializable. We will say T_i is *ordered before* T_j in a history H if, in any serial history equivalent to H, T_i occurs before T_j. Suppose T_i is ordered before T_j where $T_i \succ T_j$. If T_j commits before T_i terminates, T_i could submit some operation that conflicts with T_j. This new operation violates serializability, and since T_j has committed, T_i must abort. To avoid this priority inversion, the schedulers developed here will generate histories with the following property.

Definition 1 *A history H is* priority committed *if for all pairs of transactions T_i, T_j in H, if T_i is ordered before T_j and $T_i \succ T_j$, then $c_i < c_j$.*

A *purely aggressive scheduler* is a scheduler that never delays an operation; it rejects operations that violate its scheduling policy. A practical scheduler that generates priority committed histories will probably not be a purely aggressive scheduler. With a purely aggressive scheduler, if T_i were ordered before T_j, $T_i \succ T_j$, T_i were active, and T_j submitted a commit, a purely aggressive scheduler would have to abort T_j. This abort could be unnecessary; if instead the scheduler delayed the commit until T_i committed, the history would still be priority committed.

2 Priority Serialization Graph Testing

Serialization graph testing schedulers (or *SGT* schedulers) [6,2] guarantee serializable executions by maintaining a *serialization graph*. This graph contains nodes for all active and "relevant" committed transactions (described below). The scheduler ensures this graph contains no cycles, thus guaranteeing a serializable history.

SGT schedulers are more of theoretical than practical interest. They are easy to understand and argue correct, but the overhead of maintaining a serialization graph may not justify any increase in concurrency over other schedulers. In this section, a *SGT* scheduler will be extended to avoid priority inversions. This extension increases the complexity of the scheduler. In particular, much of the simplicity of *SGT* schedulers comes from aborting a transaction only when it submits an operation. As noted in section 1, this policy cannot be used when avoiding priority inversion.

A *SGT* scheduler operates as follows. When a transaction T_i submits an operation $p_i x$, the scheduler tentatively adds *conflict* edges from all vertices T_j to T_i if there exists an operation $q_j x$ executed earlier that conflicts with $p_i x$. If $p_i x$ creates a cycle in the serialization graph, the scheduler aborts T_i, since the resulting execution would not be serializable. Once aborted, T_i is removed from the graph along with all edges either into or out of T_i. If $p_i x$ does not create a cycle, the tentative edges can be made permanent and the operation executed.

To ensure the executed instructions are recoverable, the scheduler delays the commit from T_i until all transactions from which T_i read have also committed. Once T_i has committed, T_i can be removed from the serialization graph when it cannot be involved in any future cycles. Since all operations after T_i's commit will be ordered after T_i, any new edges will be added leading out of T_i. This means T_i can be removed when there are no edges in the graph leading into T_i. We will assume such transactions are automatically removed.

A priority serialization graph testing scheduler (or *PSGT* scheduler) follows a similar strategy, with the caveats outlined in section 1. In particular, the rejection strategy of *SGT* can cause a priority inversion. Instead of aborting the transaction that submitted the operation, we may have to abort a transaction with less priority. By generating priority commit histories, we will always be able to abort such transactions.

However, this strategy complicates the scheduler. If the submitted operation is a write, it could conflict with several unordered reads. Each new conflict can create a distinct cycle in the serialization graph. With *SGT*, all cycles are avoided by rejecting the new operation; with *PSGT*, we may have to abort a different transaction from each cycle.

Additionally, the *PSGT* scheduler will need to avoid priority inversions caused by cascaded aborts. The scheduler can do so by maintaining a *RFG* and checking for priority inversion cycles. Maintenance of a *RFG* is not as straightforward as a serialization graph. When a transaction is aborted, the *reads–from* relation changes which in turn may introduce new priority inversion cycles. For example, consider the following history where $T_0 \succ T_1, T_2, T_3$.

$$w_1x; w_2x; w_3x; r_0x$$

The only priority inversion cycle is (T_0, T_3). Once T_3 is aborted, the cycle (T_0, T_2) is created, and when T_2 is aborted the cycle (T_0, T_1) is created.

One way simplify detecting and removing priority inversion cycles is to augment the *RFG*. An *augmented RFG* will contain a vertex for each active transaction, and three kinds of edges:

1. Priority edges, as in a *RFG*.
2. Read–from edges, as in a *RFG*, except that the edge is labeled with the name of the variable that was read.
3. Write–after edges, also labeled with the name of a variable. When a transaction T_i writes a variable x, a write–after edge labeled x is drawn from the last transaction that wrote x (if it is still active) to T_i.

When a read–from edge is added to the augmented *RFG*, the graph can be traversed to determine which transactions should be aborted. Let the function Abort(T, v, p) be the set of transactions that must be aborted due to the read of variable v written by T; p is the priority of the transaction that submitted the original read operation. The functions read(T, x) and write(T, x) encode the reads–from and write–after edges; *i.e.* they are the transaction from which T read x and wrote x after, respectively. Abort is recursively defined as follows.

Abort(T, v, p) $\stackrel{\text{def}}{=}$

if p $\succ$ T $\rightarrow$ {T} $\cup$ Abort(write(T, v), v, p)
$\square$ p $\not\succ$ T $\rightarrow \forall$ variables w read by T:
$\bigcup_w$ Abort(read(T, w), w, p)
fi

Figure 2 shows an example, where write–from edges are drawn as doubled arrows. When T_1 submits r_1x, the function Abort(T_2, x, T_1) is evaluated, yielding $\{T_3, T_4\}$. T_2 will also be aborted as a cascaded abort.

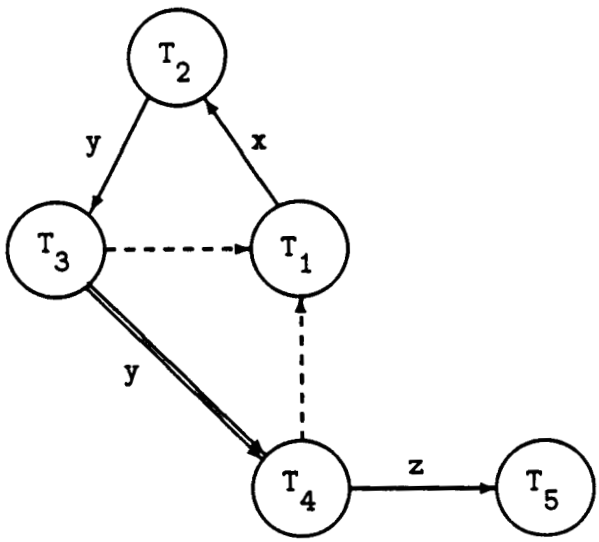

Figure 2: Abort$(T_2, x, T_1) = \{T_3, T_4\}$

A *PSGT* scheduler executes as follows. Let T_i be a transaction that has submitted an operation p_ix to the scheduler.

- If p_i is a read or write operation:

  1. Add the operation to the serialization graph as described above. Let $\mathcal{C}$ be the set of cycles created by adding the new edges. If $|\mathcal{C}| = 0$, skip to step 3.

2. If T_i can be aborted without introducing a priority inversion; *i.e.*

$$\exists c \in \mathcal{C} : \forall T_j \in c : T_i \not\succ T_j$$

then reject the submitted operation, abort transaction T_i and await the next submitted operation. Otherwise, choose a set of transactions from the cycles in $\mathcal{C}$ that, when aborted, will remove all cycles (the selection process will be described shortly); abort these transactions, and proceed with step 3.

3. Add the appropriate edge to the augmented *RFG*. If the operation is a *read*, determine the set of transactions to abort, and abort them. The transaction that must be aborted are those in Abort(read(T_i, x, T_i).

- If p_i is a commit operation, the scheduler must ensure the history is priority committed. The commit operation is delayed until all transactions ordered earlier than T_i in the serialization graph are either committed or of less or incomparable priority.

PGST maintains serializability in the same way *SGT* does; by maintaining an acyclic serialization graph. *PGST* avoids priority inversion by the (as yet unspecified) method used to select transactions to abort, described next.

Not all of the cycles in $\mathcal{C}$ need to be distinct; there can be cycles c_1, c_2 such that $c_1 \cap c_2 \supset \{T_i\}$. Note that if $c_1 \subset c_2$, c_2 is broken when c_1 is broken, and c_1 must be broken. In order to reduce the number of aborted transactions, the scheduler should examine the cycles in order of ascending length. The scheduler accumulates a list of transactions $\mathcal{A}$ to abort; if, when examining a cycle c, it is found that $\mathcal{A} \cap c \neq \emptyset$, the scheduler need not select a transaction from c to abort. Otherwise, the scheduler can choose any active transaction from c; by the property of priority committed histories, any one with less priority relative to T_i is still active.

Some issues have been glossed over for brevity. For example, the augmented *RFG* must be updated when transactions from $\mathcal{C}$ are aborted, and a transaction must be able to find the value of a variable after a cascaded abort.

3 Preemptive Two–Phase Locking

If we assume $\succ$ is connected (*i.e.* all processes have comparable priorities), two–phase locking ([3], [2]) can be easily extended to detect and eliminate priority inversion. Basic strict two–phase locking uses the following rules:

1. A transaction T_i acquires a *lock* on a data item before referencing the item. These locks are typically *read* or *write* locks (also called *share* and *exclusive* locks) depending on the submitted operation. T_i delays until the required lock is available.

2. All locks held by T_i are released after T_i commits.

In order to avoid priority inversion, a preemptive version of two–phase locking (*P2PL*) cn be used. When T_i tries to acquire a lock, it waits until either the lock is free or all processes holding the lock with conflicting access have less priority. In the latter case, the scheduler then aborts the transactions holding the lock and gives it to T_i. Since all committed transactions follow the original two–phase rules, *P2PL* generates serializable histories. Additionally, while *2PL* is susceptible to deadlock, *P2PL* limits deadlock to occur only among transaction with the same priority. If a set of deadlocked processes have different priorities, there must exist a priority inversion, and *P2PL* will detect it and remove it.

P2PL does not have cascaded aborts, so it cannot generate priority inversion cycles in the *RFG*. A transaction T_i reads from another transaction T_j only after T_j commits, and only active transactions are in the *RFG*, so the *RFG* will contain no reads–from edges.

P2PL generates priority committed histories without additional delays at commit. If T_i is ordered before T_j, either there exists two conflicting operations $p_i x < q_j x$ or there exists a transaction T_k such that T_i is ordered before T_k and T_k is ordered before T_j. For strict two–phase locking, $(p_i x < q_j x) \Rightarrow (c_i < c_j)$, and since the commits form a total order, if (T_i ordered before T_j) $\Rightarrow (c_i < c_j)$. This simplicity comes at a cost, however. For example, consider the submitted history $w_2 x; w_1 x; c_2; c_1$ where $T_1 \succ T_2$. Under *PSGT*, the commit from T_2 is delayed until after the commit of T_1; under *P2PL*, T_2 is aborted by the write from T_1.

As it currently stands, *P2PL* does not detect priority inversions with non-connected orders. Let T_1, T_2, T_3 have priorities $T_2 \succ T_3$, and let T_3 acquire an exclusive lock on x and T_1 acquire an exclusive lock on y. If T_1 attempts to acquire the lock on x it will block since $T_1 \not\succ T_3$. If T_2 then attempts to acquire the lock on y it too will block since $T_2 \not\succ T_1$. We now have T_2 transitively blocked on T_3, which is a priority inversion. Extending *P2PL* to work with partial priority orders complicates the algorithm; it must examine the owner of all locks held by processes transitively blocking the request.

4 Priority Timestamp Order

Timestamp order (*TO*) schedulers ([9], [2]) operate by assigning transactions a *timestamp* when they start. The timestamp, typically an integer, places the transaction in a total order with respect to all other transactions. The scheduler ensures operations occur in an order consistent with the total timestamp order. Since the transactions are totally ordered, the history is serializable. The scheduler typically assigns timestamps in the order the transactions start, but this is not necessary; the scheduler guarantees the operations respect any order assigned by the timestamp allocation rule.

Associated with each variable x in the data base is a *read stamp* $x.r$ and a *write stamp* $x.w$. These stamps are the timestamps of the last transaction to read and write x respectively. When T_i with timestamp s_i submits an operation to a *TO* scheduler:

1. If it is a read operation: if $s_i < x.w$ then the read is *too late* and T_i is aborted; otherwise, $x.r$ is set to s_i and the read is executed.

2. If it is a write operation: if $s_i < x.r$ then this write is *too late* and T_i is aborted; otherwise, the write is executed if $s_i > x.w$, and $x.w$ is set to s_i.

3. If it is a commit operation, it is delayed until all transactions that T_i has read from have committed. There are several ways to achieve this property ([2]).

A timestamp concurrency control algorithm that detects priority inversion (*PTO*) allocates timestamps such that priority inversion cycles in the *RFG*

cannot occur. A timestamp s_i for T_i is uniquely allocated from a total order such that it meets the following two conditions:

1. For all committed transactions T_k, $s_i > s_k$.
2. For all active transactions T_j: if $T_j \succ T_i$ then $s_i > s_j$ and if $T_i \succ T_j$ then $s_j > s_i$.

The first condition is the same as for typical *TO* schedulers: to do otherwise implies the later transaction must appear to have run *before* a committed transaction. The second condition guarantees that the *RFG* will contain no priority inversion cycles: a *reads from* edge cannot go from a transaction with less priority to one with more priority. Since the timestamps have a total order, there can be no *reads from* path from a transaction with less priority to one with more priority.

It is not difficult to generate timestamps that obey the above two conditions. If a timestamp is represented as a number, the number space must be dense. Consider transactions T_j with timestamp s_j and $T_i \succ T_j$ with timestamp $s_i < s_j$. For any n, if n new transactions start with priority between T_i and T_j, n timestamps with values $s_i < s < s_j$ must be assigned. In practice this shouldn't be a real problem, and in extreme cases the scheduler can abort T_j.

PTO must use a different comparison rule than *TO*. With *TO*, a transaction is aborted if it submits its operation too late: that is, it has too low a timestamp. Under *PTO* the transaction with more priority could be the one that is late, so the transaction that acted *too early* should be aborted. Like *PSGT*, there can be several such transactions that acted too early. For example, consider the history $w_2x; r_3x; w_1x$ where $T_1 \succ T_2 \succ T_3$. The first two operations happened too soon, and T_2 and T_3 are aborted. Instead of associating a single read and write timestamp with a variable, a list of read timestamps and write timestamps must be kept. For recoverability, each list must contain at least one timestamp from a committed transaction. This lists can grow arbitrarily long, but in practice this shouldn't be a real problem. A timestamp can be removed from a list if the list contains a larger timestamp of a committed transaction. In extreme cases, the scheduler can abort the active transaction with the largest timestamp; *e.g.* transaction T_j in the example above.

Since it is necessary to store lists of timestamps, the value of a write can also be stored with its timestamp. By doing so, fewer aborts will occur since a write can never be done too early. A database that stores histories of variables is called a *multiverison database* ([2,5]).

When T_i with timestamp s_i submits an operations, *PTO* uses the following rules:

1. If it is a read operation: s_i is entered into $x.r$. The largest entry s in $x.w$ such that $s < s_i$ is found, and the value written at that time is returned.

2. If it is a write operation: s_i is entered into $x.w$ along with the value being written. Let s be the smallest timestamp in $x.w$ greater than s_i, or ∞ if s_i is the largest timestamp. All transactions T_k in $x.r$ that have timestamps in the range $s_i < s_k < s$ are aborted (there may be no such transactions), as they read x too early.

3. If it is a commit operation, it is delayed until all transactions with timestamps less than s_i have committed. Once the transaction successfully commits, for each variable x in T_i's read (*cf.* write) set, the timestamp lists $x.r$ (*cf.* $x.w$) can be truncated: all timestamps less than s_i can be removed.

When a transaction T_j is aborted, its timestamps are removed from all variable timestamp lists. Additionally, transactions that read from T_j must also be aborted. For each variable x in T_j's write set, let s be the smallest time stamp in $x.w$ that is larger than s_j, or ∞ if no such timestamp exists. All transactions T_k in $x.r$ such that $s_j < s_k < s$ read from T_j, so they are aborted.

PTO ensures serializability by using timestamps from a total order, and ensures there are no priority inversions for recoverability by its timestamp generation rule. The main weakness with *PTO* is the delay in the commit rule. Suppose a transaction only wishes to update x but is started at the same time a long–running transaction with more priority is active. Even if the two transactions never reference the same variables, the shorter transaction must wait for the longer running transaction to complete. With both *P2PL* and *PSGT*, the shorter transaction will be able to complete

without delay. For *PTO* to do similarly, it must either maintain the actual *reads from* relation as *PSGT* does, or know more information about the transactions (such as a transaction's read set and write set).

5 Discussion

This paper examined three common concurrency control algorithms and showed how each could be extended to avoid priority inversion. The results are mixed:

- Without some knowledge of the transactions that will be submitted, there are no purely conservative concurrency control schedulers nor any practical purely aggressive concurrency control schedulers that avoid priority inversion.
- Traditional aggressive schedulers, like serialization graph testing and timestamp order schedulers abort a transaction by rejecting an operation when submitted. This method cannot be used when priority inversion must be avoided. Instead, a transaction that submitted its operation earler must be aborted, so the more urgent transaction can continue. This policy increases the complexity of aggressive schedulers. In the case of serialization graph testing, it isn't clear that the increased concurrency would ever compensate for the increased complexity, given a reasonable workload.
- The traditional conservative scheduler, two phase locking, can be easily extended to avoid priority inversion when the priority relation is connected. The extension for nonconnected priorities is somewhat more complex.
- Timestamp order schedulers, when extended to avoid priority inversion, suggest using a multiversion concurrency control algorithm. The extended algorithm is not much more complex than a traditional multiversion timestamp order algorithm. However, transactions with less priority can be needlessly delayed unless read sets and write sets are declared when a transaction starts.

The algorithms presented here have not been implemented, and their relative performance has not been examined in any detail. Additionally, only the priorities of transactions has been to schedule or abort operations. Other information could be used, such as the remaining running time of a transaction ([1]). It isn't clear what kind of information would be useful for the more aggressive schedulers.

These algorithms were developed as part of the Cornell *RR Project*, where which we are developing both theory and tools for building real–time reliable systems. Part of this project is the development of a process control system, which will eventually contain a database–like component. Our next step with the algorithms in this paper will be to evaluate them in the context of the *RR* project.
